

Pointers

What is pointer? - Address of the variable or location of data.

Size of pointer = size of address = 2^{32} bits = 4 bytes

What is pointer? - A pointer is a variable which stores address.

As pointer stores the address an address is always integer means pointer size is always of 4 bytes.

2)

TYPES OF POINTERS

In old operating system (Real mode) there are three types of pointers are

- 1) Near pointer
- 2) Far pointer
- 3) Huge pointer

Why? - These types of pointers are not applicable in today's operating system because the latest OS works in protected mode.

pointer

; 2GB

huge
(1024---)

(640-1024)

FAR
(0-640 Kb)
Near

1024 Kb

640 Kb

0 Kb

If pointer points in between 0 to 640 kb then it is near pointer.

If pointer points in between 640 - 1024 kb then it is far pointer.

If pointer points 1024 kb and above it is huge pointer.

All these types are not applicable in latest operating system.

For more details refer my file

3) pointer creation is behaviour of compiler.

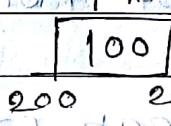

To create the pointers we have to use special operator (*).

* is considered as the reference operator.

To store the address inside pointer we have to use address of operator (&).

int no=10;

int *p=&no;

no is a variable of type integer currently initialised with value 10.

p is a pointer which holds the address of integer, currently it holds address of no, where no is the variable of type integer initialised with value 10.

printf("%d", no); // 10

printf("%d", &no); // 100

```

d1) printf("%d", p); // 100
printf("%d", &p); // 200
d2) printf("%d", *p); // 110

```

4) The reference operator $\&$ ($*$)

To create the pointer we have to use this operator.

If we want to access the contents of the pointed data then we use $*$ operator to fetch its value.

In above example when we specify $\&P$ we get the result as 11 because 11 is the value which is stored in variable no and address of no is stored in our pointer P.

5) Types of pointer according to data type

We can create a pointer which points to any primitive data type (char, int, float, double).

We can create a pointer which points to any derived data type (array, pointer function).

We can create a pointer which points to any user-defined data type (structure, union, Enumeration).

1) $\text{int no} = 11;$ $\text{int *p} = \&\text{no};$

$\text{float f} = 3.14;$ $\text{char ch} = 'A';$ $\text{double d} = 7.10;$

$\text{p} [200]$

$200 \quad 208$

2) $\text{char ch} = 'A';$ $\text{char *q} = \&\text{ch};$

$\text{ch} [A]$

$300 \uparrow 301$

$\text{q} [300]$

$400 \quad 408$

3) $\text{float f} = 3.14;$ $\text{float *x} = \&\text{f};$

$f [3.14]$

$500 \uparrow 504$

$x [500]$

$600 \quad 608$

4) $\text{double d} = 7.20;$ $\text{double *y} = \&\text{d};$

$d [7.20]$

$700 \uparrow 708$

6) size of operator $\$$

This operator is used to fetch the size of any specific variable of any data type.

e.g. $\text{int no} = 11;$

$\text{float f} = 3.14;$

$\text{double d} = 7.10;$

$\text{char ch} = 'A';$

$\text{int *p} = \&\text{no};$

$\text{float *q} = \&\text{f};$

$\text{char *x} = \&\text{ch};$

$\text{double *y} = \&\text{d};$

```

printf ("%d", sizeof (no)); // 4
printf ("%d", sizeof (d)); // 8
size of (ch); // 1
size of (p); // 8
size of (int); // 4
size of (float); // 4
size of (double); // 8
size of (x); // 8
size of (y); // 8
size of (*p); // 4
size of (*x); // 1
size of (*y); // 8
size of (3.14); // 8
size of (11); // 4
size of (3.14f); // 4

```

- 7) we can create pointer to pointer, pointer to pointer means our pointer holds address of another pointer.

`int no = 11; int *p = &no;`

Address of no is 100 and value is 104

`int *p = &no;`

Address of p is 200 and value is 100

`int **q = &p;`

Address of q is 300 and value is 200

`int ***x = &q;`

Address of x is 400 and value is 300

`int ****y = &x;`

Address of y is 500 and value is 400

```
printf ("%d", no); // 11  
printf ("%d" & no); // 100  
printf ("%d" & p); // 200  
printf ("%d", *p); // 1100  
printf ("%d", &x); // 400  
printf ("%d" & *y); // 200  
printf ("%d", &q); // 300  
printf ("%d" * q); // -11  
printf ("%d" *** x); // 11  
printf ("%d", *** y); // 1000  
printf ("%d", *** y); // 200  
printf ("%d" & (*y)); // 300  
printf ("%d" & (*x)); // 100  
printf ("%d" & (*q)); // 200
```

8) Real mode vs protected mode

- This are the two types of modes in which the operating system executes.
- In case of Real mode only single process executes at a time, whereas in case of protected mode more than one process executes at a time.
- In case of Real mode first mb of the memory is accessible whereas in case of protected mode, the whole RAM is accessible.
- In case of Real mode if first process is running then all the other processor are in waiting state. But in case of protected

mode multiple process can execute simultaneously.

- In today's operating system we start in a real mode and shift into the protected mode at time of shutdown again our os goes into the real mode.

9)

NULL pointer

When we create any variable it gets initialized with its default value.

But in case of pointer we have to initialise it with an inbuilt keyword, i.e. NULL.

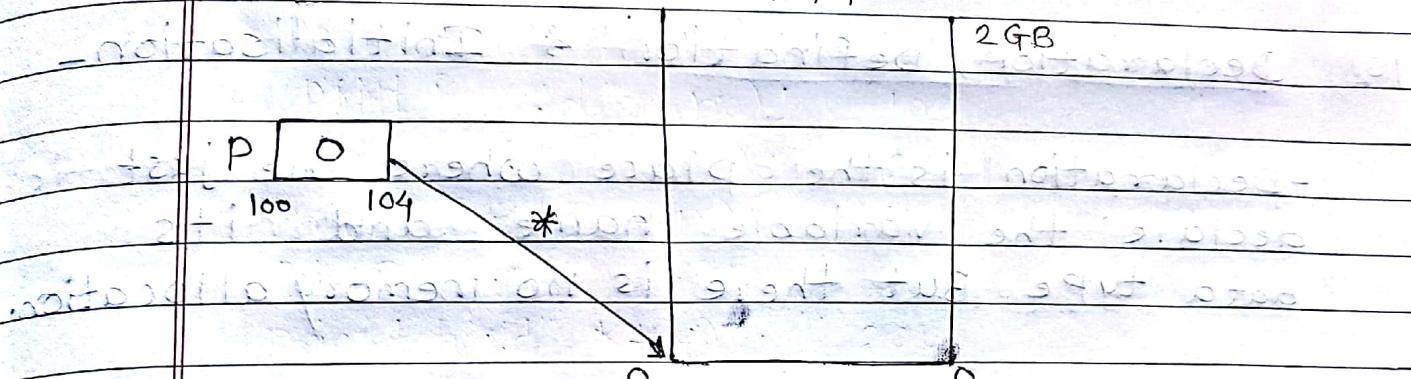

It is considered as good programming practice to initialise pointer to NULL because it avoids runtime accidents.

In almost every header file of C programming NULL is an inbuilt macro which is internally defined as.

```
#define (void *) 0
```

According to above syntax we conclude that void pointer is a pointer which points to the zeroth (0th) address of our RAM.

RAM

eg. If we want to initialise the pointer to a specific value then there is no need to initialise it with NULL.

```
int no = 11;
int *p = &no;
```

consider the below syntax where we create the pointer and then initialise it with the NULL.

```
int *p = NULL; // definition
int no = 11; // definition
// code
```

`p = &no; // initialisation`

NULL is used to initialise an uninitialised pointer.

It is good programming practice to initialise every pointer NULL.

10)

Declaration, Definition & Initialisation.

- Declaration is the place where we just declare the variable name and its data type. But there is no memory allocation.

- As there is no memory allocation we can't initialise at the point of declaration.

- Definition :-

It is the place where we allocate the memory.

As we allocate the memory we can also initialise with some values.

Initialisation :-

Initialisation means storing some value into the allocated memory.

e.g.

① ~~Extern int i;~~ // Declaration

~~int j;~~ // Definition

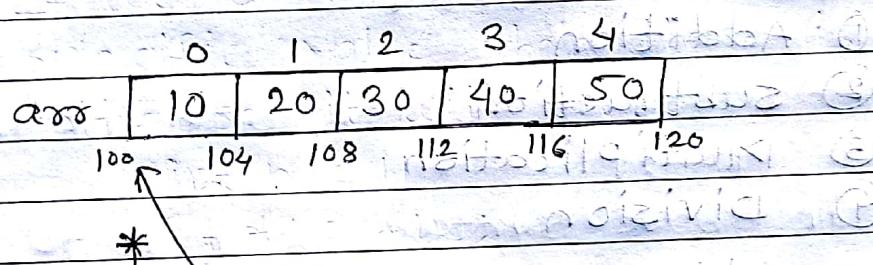

~~int k=21;~~ // Definition with initialisation

~~extern int a=25;~~ // not allowed

ii) We can create a pointer which points to an array.

example -

```
int arr[5] = {10, 20, 30, 40, 50};  
int *p = NULL;
```

- According to above dia. our pointer p points to the base address of the array (address of first element)

- Like the above syntax, we can create any type of pointer which points to its specific type of array.

2.12) pointer Arithmetic

- Pointer arithmetic means the arithmetic operations that we can perform on the pointers.

$$INT = 4 \times 32$$

- There are four types of arithmetic operations are:

- ① Addition
- ② Subtraction
- ③ Multiplication
- ④ Division

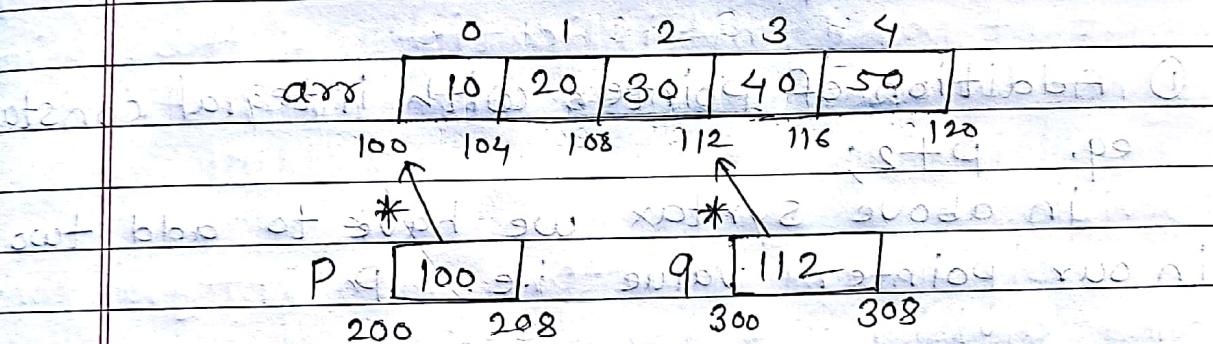

From Above 4 operations some operations are allowed on pointers and some operation are not allowed due to memory restrictions.

Addition	Subtraction	Multiplication	Division
✓	✓	✗	✗
① Pointer + no	① Pointer - no	① Pointer multiply by no.	① Pointer / no
② Pointer + pointer	② Pointer - pointer	② Pointer multiply by pointer	② Pointer / pointer

example :-

```

int arr [] = {10, 20, 30, 40, 50};
int *p = NULL;
int *q = NULL;
p = arr; // p = &(arr[0]);
q = &(arr[3]);
    
```

```

printf ("%d", arr);           // 100
printf ("%d", &arr);          // 100
printf ("%d", arr+1);         // 104
printf ("%d", arr+3);         // 112
printf ("%d", (&arr)+1);      // 120
printf ("%d", &(arr[0]));     // 100
printf ("%d", &(arr[4]));     // 116
printf ("%d", p);             // 100
printf ("%d", q);             // 112
printf ("%d", *p);            // 10
printf ("%d", *q);            // 40
printf ("%d", *(p+2));        // 30
printf ("%d", *(q+1));        // 50
printf ("%d", *(q-2));        // 20
printf ("%d", q-p);           // 3
    
```

```

printf("y.d", p*2); // error
printf("y.d", p+q); // error
p*q; // error
p/3; // error
p/9; // error

```

I) Addition of pointer

① Addition of pointer with integral constant

eq. $p+2;$

in above syntax we have to add two
in our pointer value i.e. $p+2;$

$p+2 * \text{sizeof}(\text{int});$

$\text{or } p+2 * 4;$ (as $\text{sizeof}(\text{int}) = 4$)

$\text{or } p+8;$ (as $\text{sizeof}(\text{int}) = 4$)

$\text{or } 100+8;$ (as $\text{sizeof}(\text{int}) = 4$)

$\text{or } 108;$ (as $\text{sizeof}(\text{int}) = 4$)

$\text{or } (100+2) * \text{sizeof}(\text{int})$ (as $\text{sizeof}(\text{int}) = 4$)

Due to the Above Syntax the value of
the pointer is not modified because we
are not updating with its initial value.

To update the value of pointer we
have to write below syntax as

$P = P + 2;$ ($\text{P} = \text{P} + 4$)

$P = P + 2 * (\text{sizeof}(\text{int}));$

$P = P + 2 * 4;$ ($\text{P} = \text{P} + 8$)

$P = P + 8;$ ($\text{P} = \text{P} + 16$)

$P = 100 + 8;$ ($\text{P} = \text{P} + 16$)

$P = 108;$ ($\text{P} = \text{P} + 16$)

After this syntax our p pointer points to the address 108.

② Addition of two pointers:

eg. $p+q;$ // not allowed

due to memory restriction it is not allowed.

② Subtraction of pointers:

① Subtracting integral const from pointer.

eg.

$\text{int} q = 9 + 20;$

or $q = q + 2 * \text{sizeof(int)};$

$q = q - 2 * \text{sizeof(int)}$

$$q = q - 8$$

$$q = 112 - 8;$$

$$\text{sizeof}(q) = 104$$

In above syntax sizeof(int) indicates the size of pointer type.

② Subtracting two pointers from each other:

eg. $q - p$

$(q - p) / \text{sizeof(int)};$

$(q - p) / 4;$

$(112 - 100) / 4;$

$$12 / 4$$

$$3$$

$$3 = q - p$$

In above syntax we divide by size of pointer.

- Subtraction of two pointers is allowed if both the pointers are pointing to some memory region (some array).
- Both the pointers should be of some type.

3) Multiplication -

Multiplication of pointer with integral constant and multiplication of two pointer is not allowed due to memory restrictions.

4) Division -

Division of pointer with integral const. and division of two pointer is not allowed because of the memory restriction.

$q * 2;$ } ~~not allowed~~
 $p * 2;$ } ~~not allowed~~

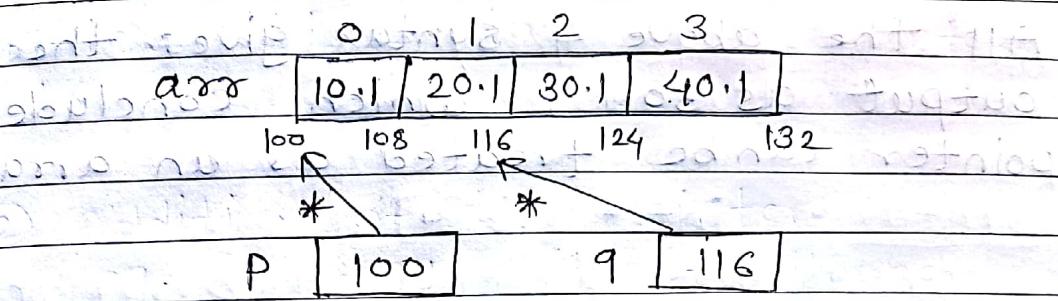

p / q } ~~not allowed~~
 $p / 3$ } ~~not allowed~~

13) Array is internally considered as pointer

when we consider the array, its address gets considered automatically by the operating system.

eg. $\text{double arr[]} = \{10.1, 20.1, 30.1, 40.1\};$
 $\text{double *P} = \text{NULL};$

$\text{P} = \text{arr};$ ~~rib sui zutne ka mode nہیں~~

`double *q = &(arr[2]);`

consider the below syntax of arrays as

`arr[2];`

\downarrow

~~`*(&arr+2);`~~ is a pointer to base arr

\downarrow

~~`*(&arr+2);`~~ is a pointer to arr

\downarrow

~~`2[arr];`~~

All the above syntax gives the same output.
ie. 30.1 which concludes that array is internally considered as pointer.

Q) An array is considered as pointer we can also treat pointer as array.

consider the same Example as above.

`(*(&s)).*(&p+2);`

`*(&2+p);`

`P [2];`

`2 [P];`

All the above 4 syntax gives the same output as 30.1021 which concludes that pointer can be treated as an array.

15) Incrementation & Decrementation of pointer.

1) $++$, $--$ are considered as the increment and decrement operators.

e.g. ~~int no=10;~~ ~~no = 10~~ ~~10~~

int no = 10; no [10] 11
[10] 100 [11] 100 104

no++;

The above syntax is internally treated as,

int no = 20; (no) [20] 19

[20] 200 [19] 204

no--; ; [no] 18

above syntax is internally treated as,

no = no - 1; ; [no] 19

Like above operation on integer we can perform the same operation on pointer.

Syntax for char arr[] = { 'A', 'B', 'C', 'D' };

char *p = arr;

char *q = &(arr[2]);

; [q] 95

; [q] 20

0 1 2 3

arr [A | B | C | D]

100 101 102 103 104

P [100 101] P q [102 103]

200 208 300 308

printf ("%c", *p); // A

p = p + 1;

p = p + 1 * (sizeof(char));

p = p + 1; i2 = i + 1

p = 100 + 1; i2 = i + 1

p = 101; i01 = i + 1

printf ("%c", *p); // B

printf ("%c", *q); i + 1 / 2 [C]

q = q - 1; i2 = i + 1 / 2

q = q - 1 * (sizeof(char));

q = q - 1 * 1

q = 102 - 1

q = 101; i01 = i + 1 / 2

printf ("%c", *q); // B

001 111 1100

101 111 1100

111 111 1100

001 111 1100

16) We can create array of pointer like array of primitive data types

Syntax : `int *arr[4];`

arr is one dimensional array which contains four elements, each element is of type `int*`.

In simple terms arr is array of pointers

`int i = 11; // i + 4 = 15`

`int j = 21; // j + 4 = 25`

`int k = 51; // k + 4 = 55`

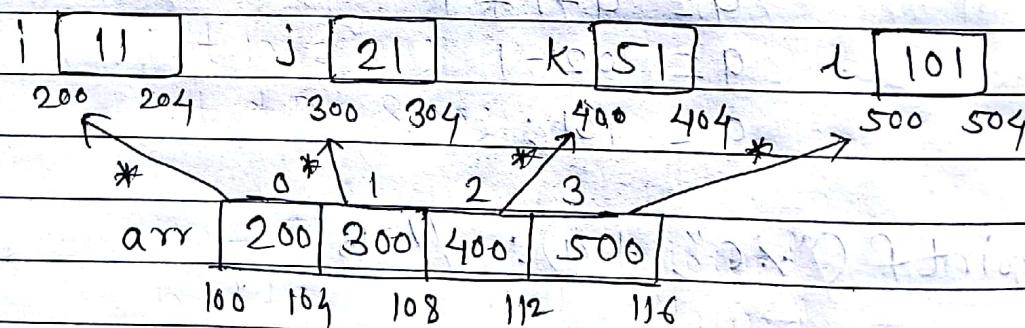

`int l = 101; // l + 4 = 105`

`arr[0] = &i;`

`arr[1] = &j;`

`arr[2] = &k;`

`(arr[3]) = &l;`

`print ("%d", arr); // 100`

`&arr;` // 100

`arr+1;` // 104

`&arr+1;` // 116

`arr[0]` // 200

```

arr[3];           // 500
&arr[2];          // 108
*(arr+1);         // 300
*(arr[2]);        // 21
&j;               // 300
j.R;              // s+11.51
*(*(arr+2));     // ([s]+11.51)
*(2+arr);         // 400
*(3[arr]);        // 101
*(*(2+arr));     // 51

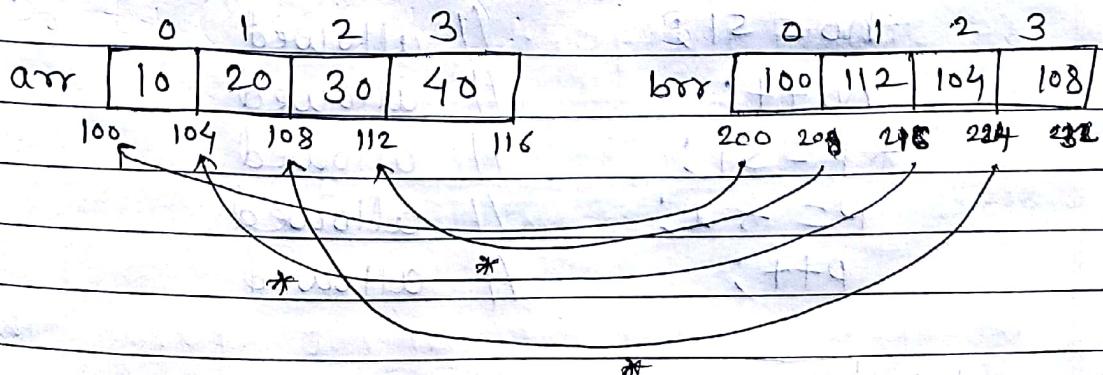

```

- Q17) We can create array which contains pointers in it. where that pointer points to the another member of array.

```

int arr[4] = {10, 20, 30, 40};
int *brr[4];
brr[0] = arr; // arr is of size 4
brr[1] = &(arr[3]);
brr[2] = arr+1;
brr[3] = arr+2;

```

```

printf("%d", arr); // 200
arr[0]; // 100
arr[1]; // 104
arr[1] = 20;
arr[2]; // 104
arr[2] = 216;
*(arr+2); // ((20+0)+2)
*(arr+2+0); // (20+0)
*(arr+2+1); // 30
    
```

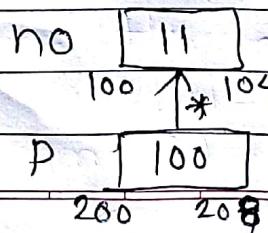

18) Constant with pointer &

In this section we can use the concept of constant with the concept of pointer. In this case constant is considered as data type qualifier due to which we can not change the value of any variable.

There are four different variations. as

- int no = 11; and int *p = &no;

no = 51;	// allowed
no++;	// allowed
*p = 51;	// allowed
p = &x;	// allowed
p++;	// allowed

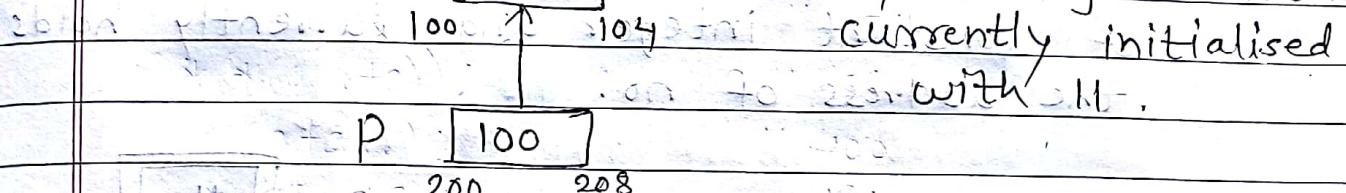

2) `const int no = 11;`

`const int *p = &no;`

(`no = 41`) \rightarrow true

\Rightarrow `no` is variable of

type integer constant

`p` is a pointer which holds the address of integer constant, currently it holds address of `no`.

`no = 51;` // not allowed

`no ++;` // not allowed

`*p = 51;` // not allowed

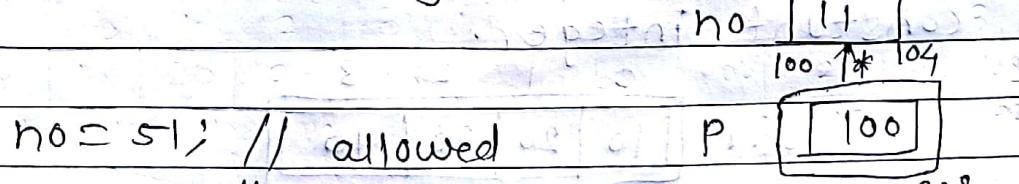

`int *p = &x;` // allowed

`p ++;` // allowed

3) `int no = 11;`

`int *const p = &no;`

\Rightarrow `p` is a constant pointer which holds address of integer

`no = 51;` // allowed

`no ++;` // allowed

`*p = 51;` // allowed

`p = &x;` // not allowed

`p ++;` // not allowed

because `p` is const

because `p` is const

$n = [0] \text{ m}$

$\text{++}([0] \text{ m})$

4) `const int no = 11; int *p;`

`const int *const p = &(no);`

`// int const *const p = &no;`

To understand \leftarrow

\Rightarrow `p` is constant pointer which holds address of constant integer and currently holds the address of `no`.

`no = 51;`

`no++`

`*p = 51;`

`p = &x;`

`p++;`

`no`

`*`

`200`

`208`

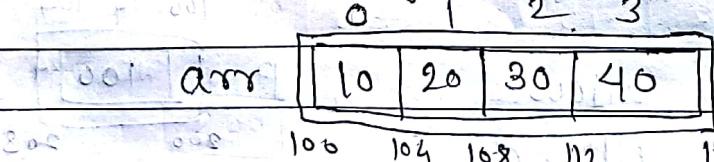

above syntax demonstrate the concept of pointer with the concept of constant.

19) we can create the array of constant.

syntax :-

`const int arr[4] = {10, 20, 30, 40};`

\Rightarrow `arr` is one dimensional array which contains four elements each element is of type constant integer.

in above syntax we can not change the value of the elements of array.

`arr[0] = 11;` // not allowed

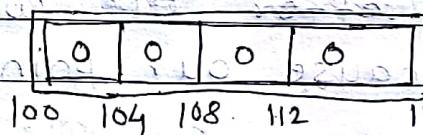

`(arr[0]) ++;` // not allowed

20) If array is constant array then it should be initialise immediately by using the concept of member initialisation list.

To the constant array member by member initialisation is not allowed.

`const int arr[4];`

If the above array is global then its default value i.e. (0) is considered as constant value.

21) Generic pointers (void*)

- There are two types of pointer as specific pointer and generic pointer.

- In case of specific pointer the type of pointed data type is already known.

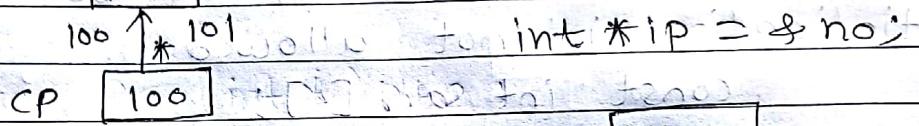

- but in case of generic pointer type of pointed data type is not known.

- If we create character pointer, int pointer, float pointer, double pointer, then the type of pointed data type is already known.

- In case of generic pointer we just create the pointer section of the pointed data type.

bluenote now `char ch = 'A'`,
so `char *cp = &ch;`

meanwhile `ch` \boxed{A} \rightarrow `int no = 11;`

`200 208`

`no` $\boxed{11}$

`300` \uparrow 301

`ip` $\boxed{300}$

`400 408`

when we dereference `CP` we can fetch only one byte because our pointer is character pointer.

similarly, when we dereference `ip` we can fetch four bytes because our pointer is integer pointer.

so now `char ch = 'A'`, `int no = 11;`

`void *cp = &ch;` `void *ip = &no;`

so `CP` \rightarrow `ch` \boxed{A}

`300 308`

`100 101`

`ip` $\boxed{200} \rightarrow$ `no` $\boxed{11}$

`400 408`

`200 202`

`printf("%c", *cp)` // error

in above syntax there is an error because `void`

pointer. Unable to decide how many bytes to fetch. To avoid this problem we can use the concept of type casting.

Type casting is the concept where one data type gets converted into another data type in a temporary format.

```
printf("%c", *(char*)cp); //ok
printf("%d", *ip); //error
printf("%d", *(int*)ip); //ok
```

22) Pointer Arithmetic on void pointer.

We have to consider the addition and subtraction operation on the pointer.

```
int arr[4] = {10, 20, 30, 40};
```

0	1	2	3
100	104	108	112

```
void *P = arr; //arr is an array
```

P	100
200	208

```
printf("%d", *P); //error
```

P	100
200	208

```
* (int*) P; // 10
```

```
int p = pt2; //error
```

above syntax generate error because we perform pointer arithmetic of void pointer.

But in case of void pointer the size of pointer type is not known.

- To avoid this we have to perform typecasting as

$p = (int *) p + 2;$

Due to the above typecasting our pointer incremented by 8 byte.

For every pointer arithmetic we have to use concept of typecasting.

If we perform incrementation as

$p++;$ it generates error because our pointer is void pointer.

on some compiler increment operator on void pointer increments its value by one

To avoid this we have to update our syntax as

$++(int *) p;$

Note :-

If data type is not known then we can create the void pointer otherwise we can create specific pointer.

23) Function pointer :-

- ① It is a type of pointer which points to the base address of the function.
- ② When we compile the program all compile instructions gets stored into the text section. means our function's pointer points to the text section.

```
int add (int, int);  
          ↓   ↓   ↓   ↓   ↓ : o = tan - ni  
int (*fp) (int, int);
```

add is a function which accepts two parameters first is integer and 2nd is integer, that function returns integer.

fp is a pointer (which) points to a function which accepts two parameters, first is integer, second is integer & that function returns integer.

In C Programming there are two technical concepts where the name is indirectly considered as address.

Name of the array and name of the function is internally considered as the address.

// Demo.c

```
#include <stdio.h>
int add(int, int);
int sub(int, int);

int main()
{
    int x = 10;
    int y = 5;
    int ret = 0;
    int (*fp)(int, int) = add;
    ret = fp(x, y); // ret = add(10, 5)
    printf("%d\n", ret);
    fp = sub;
    ret = fp(x, y); // ret = sub(10, 5)
    printf("%d\n", ret);
    return 0;
}

int add(int no1, int no2) // 1000
{
    int ans = 0;
    ans = no1 + no2;
    return ans;
}
```

int isab(int no1, int no2) // 2000

{

int ans = 0;

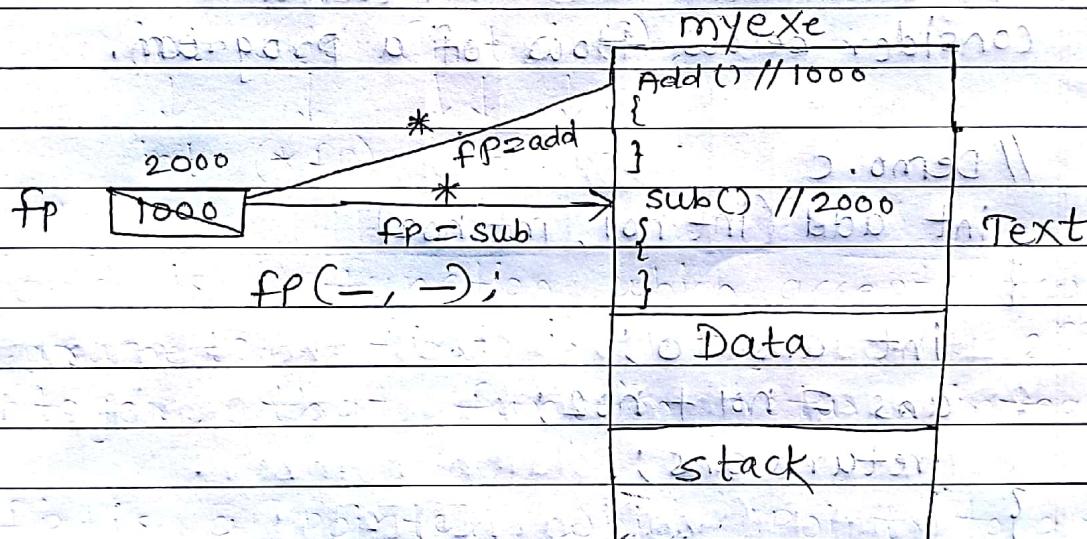

ans = no1 - no2;

return ans;

}

gcc demo.c -o myexe

/c. myexe

The concept of function pointers is used in case of dynamic link library.

To create the function pointer first we have to consider the prototype of the function.

Like the other pointers function pointer also requires four bytes of memory.

Internal mechanism of function pointer:

- When we write the function it gets converted into assembly language - and = assembly lang. function gets converted into the binary language.

- When we create function pointers our pointer points to the function instruction of a function in text section.

Consider below flow of a program.

```
// Demo.c
int add(int no1, int no2)
{
    int ans = 0;
    ans = no1 + no2;
    return ans;
}
```

// Demo.asm

```
ADD: add.void void add(int no1, int no2)
    mov EAX, no1
    mov EBX, no2
    add EAX, EBX
    RETURN EAX
```

// demo.obj // demo.exe

57 05 08

0110 1011 0110

11000

57 06 09

1101 1011 0111

61 05 06

1000 0100 1111

65 05

1011 1101

In above program the base address our function is thousand.

If you want to store the address of that function then we have to create its function pointer.

int Add (int, int)

int (*fp) (int, int)

Now we have to store address of add function

into the fp pointer.

fp = Add; // fp = 1000;

now we can call the function by using function pointer fp as

ret = fp(10,5); //Add(10,5)

In case of function pointer there is no need to use * operator to dereference the data like the other pointers.

By using the function pointer we can call the targeted fun whose address is stored in our pointer.

Multidimensional Array

Code No: 010

80 20 F2

It is considered as array of array.

e.g. int arr[3][5];

→ arr is two dimensional array, which contains three one dimensional array, each one dimensional array contains five elements, and each element is of type integer.

Diagrammatic representation:

	0	1	2	3	4	5	6	7	8	9
0										
arr			(tri)							
1										
2										

(tri, tri), (tri) tri

If you want to access the element from 2D array, then we have to specify its row number and column number.

printf("%d", arr[1][2]);

As one dimensional array is internally considered as pointer, we can also represent 2D array as a pointer.

① Arr [3] [5];

⇒ *(* (Arr + 3) + 5);

② Arr [3] [2];

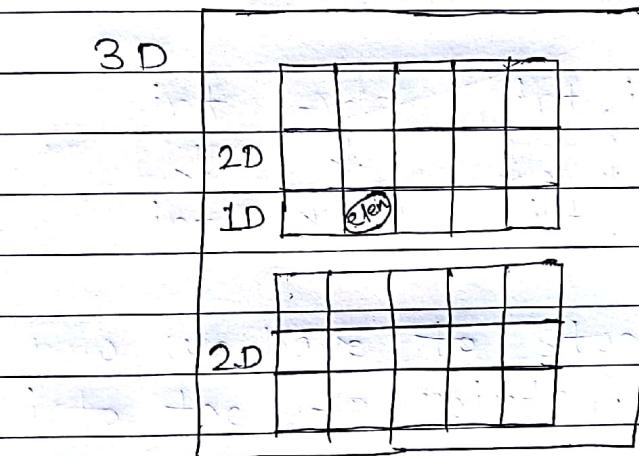

⇒ *(* (Arr + 3) + 2);

Like the 2D array we can also create 3D array as

`float arr [3] , [5] [6];`

\Rightarrow arr is 3D array, which contains 3 two dimensional array, each 2D array contains 5 one dimensional array, each 1D array contains six elements and each elements is of type float.

`double arr [2] [3] [5];`

arr is 3D array which contains two 2D array, each 2D array contains 3 one dimensional array each 1D array contains 5 elements and each elements is of type double.

`Arr [2] [1] [3];`
pointer representation as

`* (* (* (Arr+2) +1) +3);`
